## **ULTRA-LOW POWER PROGRAMMABLE TIMER AND LOW VOLTAGE DETECTION CIRCUITS**

### **Related Patent Application**

[0001] This application claims priority to commonly owned United States Provisional Patent Application Serial Number 60/476,323; filed June 6, 2003; entitled "Ultra Low Power Microprocessor Timer and PLVD Circuit," by Ruan Lourens and Miguel Moreno, which is hereby incorporated by reference herein for all purposes.

### **Field of the Invention**

[0002] The present invention relates generally to low power battery operated devices, and more particularly to ultra-low power programmable timer and low voltage detection circuits.

### **Background of the Invention Technology**

[0003] Low power consumption is absolutely critical in digital electronic applications that use batteries as a power source and in most of these applications current drawn while in a sleep mode dictates the battery life of the application. Thus, it is critical to have a very low current drain while in the sleep mode and a low power way to wake up from the sleep mode in a timed manner. Existing wake-up timers that are based on traditional oscillators consume too much power for most lithium battery applications and may consume several microamperes of current. One solution was to use a resistor capacitor (RC) timer that woke up the digital circuit, *e.g.*, digital processor, on a "wake-up on change" event, however, existing digital input structures consume high crowbar currents with a slowly changing input signal.

[0004] For some applications it is desirable to have a variable wake-up period that can be controlled with a digital processor.

[0005] In battery operated applications a low power programmable low voltage detection (PLVD) circuit is highly desirable but is often omitted due to price and power considerations.

[0006] Low power wake-up timers use passive resistor-capacitor timing circuits having slowly rising voltage levels that go toward  $V_{DD}$ . The problem with these types of timer circuits is that a leaky capacitor when used in a low power mode (high resistor value) may never wake up the device when the leakage current of the capacitor and the input leakage into the device connection exceeds the drive capability of the resistor. This problem may be aggravated at high temperatures, thus making operation of this type of timer unpredictable.

[0007] Therefore, what is needed are ultra-low power programmable timer and low voltage detection circuits that consume very little power and are accurate and reliable over the entire useful temperature range of a device.

### **SUMMARY OF THE INVENTION**

[0008] The invention overcomes the above-identified problems as well as other shortcomings and deficiencies of existing technologies by providing an ultra-low power circuit that can be used to implement, in a digital integrated circuit device, a basic timer, programmable timer and programmable low voltage detection (PLVD) using a single connection, *e.g.*, pin, ball, pad, tab, surface mount wing and the like, of the digital integrated circuit device and a passive component(s) external to the digital integrated circuit device. An internal low current source may be enabled so as to discharge an external capacitor coupled to the connection, thus eliminating the need for an external resistor. However, timing accuracy may be improved by adding an external discharge resistor since the internal current source may be more process and temperature dependant than the external discharge resistor. The connection may be configured

as a tri-state output and may be driven high to charge the capacitor. An analog voltage level detection circuit and, optionally, the current source may be enabled when the digital integrated circuit device is placed into a sleep mode. During the sleep mode, the external capacitor slowly discharges through the voltage level detection circuit and/or current source (and/or the external resistor), and when a low voltage threshold value is reached, a voltage level comparison circuit in the voltage level detection circuit causes a logic level change that activates ("awakens") the digital integrated circuit device from its sleep mode. The digital integrated circuit device may be a digital processor, *e.g.*, microprocessor, microcontroller, programmable logic array (PLA), programmable gate array (PGA), application specific integrated circuit (ASIC), and the like.

[0009] Preferably, only a single output connection and external capacitor are required to realize basic timer, programmable timer and PLVD functions. Thus the invention is well suited for cost sensitive applications. The invention circuit detects an analog signal level relative to some threshold or trigger voltage. This enables implementation of ultra-low power timer and PLVD functions, without the high crowbar currents associated with a digital input signal slowly changing from one supply voltage rail to the other.

[0010] Timing accuracy of these functions may be improved by adding a single discharge resistor instead of using the internal current source. For programmable timing, an additional charging resistor may be added for more accurate charging of the capacitor to a certain voltage over a predefined time period. Many lithium battery applications require about one microampere of timed sleep current and even the lowest powered clock oscillator based timer circuits consume at least several microamperes. Preferably, the invention has a maximum current consumption of

about 350 nanoamperes or less, thus leaving a couple of hundred nanoamperes of standby current available for the digital device when in the sleep mode.

[0011] Temperature may be determined from the relationship between the voltage reference and internal current source. The parameters for the voltage reference and the internal current source are dependent upon temperature and process variations during manufacture of the invention. The process variations may be measured when the invention circuit is first turned on under controlled conditions. Measured values corresponding to temperature variations may be determined and stored in a memory, *e.g.*, electrically erasable programmable read only memory (EEPROM), Flash memory and the like, for later use in determining temperature from the invention. The temperature dependency of the voltage reference is substantially linear, however, the internal current source may have a significant second order term, but if the temperature deviation is relatively small, this second order term may be ignored.

[0012] A technical advantage of the invention is ultra-low power operation. Yet another technical advantage is the need for a minimum number of external components. Another technical advantage is low cost. Still another technical advantage is very low current discharge of timing circuit. Still another technical advantage is use of an existing output connection of an integrated circuit package. Yet another advantage is temperature sensing by using the reference voltage and internal current source temperature dependencies.

[0013] Features and advantages of the invention will be apparent from the following description of the embodiments, given for the purpose of disclosure and taken in conjunction with the accompanying drawing.

**BRIEF DESCRIPTION OF THE DRAWING**

[0014] A more complete understanding of the present disclosure and advantages thereof may be acquired by referring to the following description taken in conjunction with the accompanying drawing, wherein:

[0015] Figure 1 illustrates a schematic diagram of a circuit for an ultra-low power timer or a programmable low voltage detector (PLVD), according to exemplary embodiments of the present invention.

[0016] While the present invention is susceptible to various modifications and alternative forms, specific exemplary embodiments thereof have been shown by way of example in the drawings and are herein described in detail. It should be understood, however, that the description herein of specific embodiments is not intended to limit the invention to the particular forms disclosed, but on the contrary, the intention is to cover all modifications, equivalents, and alternatives falling within the spirit and scope of the invention as defined by the appended claims.

**DETAILED DESCRIPTION OF SPECIFIC EMBODIMENTS**

[0017] Referring now to the drawings, the details of exemplary embodiments of the present invention are schematically illustrated. Like elements in the drawing will be represented by like numbers, and similar elements will be represented by like numbers with a different lower case letter suffix.

[0018] Referring to Figure 1, depicted is an ultra-low power timer or a programmable low voltage detector (PLVD), according to exemplary embodiments of the invention. The invention

comprises an ultra-low power voltage detection and logic module, generally depicted by the numeral 102, and an external component(s), *e.g.*, timing capacitor 126, resistor 124 and resistor 122. An output connection 120 (*e.g.*, pin, ball, pad, tab, surface mount wing and the like) of a digital integrated circuit device 100, is coupled to a tri-state output circuit comprising transistors 118 and 116. The ultra-low power voltage detection and logic module 102 comprises a very low current internal current source 104 having an enable input 128, an analog comparator 106 (*e.g.*, high gain differential amplifier) having an input connected to the external connection 120 and another input connected to a voltage reference 112, and digital logic 108 having a digital output 110 and an input connected to an output of the comparator 106. The module 102 may be part of the digital integrated circuit device 100. Resistors 122 and 124 are optional and the invention operates satisfactorily without these resistors. The resistors 122 and 124 preferably may enhance functionality of the invention.

[0019] The comparator 106 determines whether an analog signal on connection 120 is less than or equal to, or greater than the reference voltage 112. The output of the comparator 106 drives the logic 108 so that its output 110 is at a first digital logic level when the analog signal at connection 120 is less than or equal to the reference voltage 112, and at a second digital logic level when the analog signal is greater than the reference voltage 112.

[0020] According to an exemplary embodiment of the invention, a basic timer may be implemented by coupling the capacitor 126 to connection 120. The internal current source 104 remains disabled with by a disable signal to the enable input 128. Connection 120 is defined as a digital output through transistors 116 and 118, and the capacitor 126 is charged to substantially a rail voltage 130, *e.g.*,  $V_{DD}$ . Once the capacitor 126 is substantially charged to the rail voltage

130, the transistors 116 and 118 are turned off (tri-stated) or otherwise decoupled from the connection 120, the module 102 is enabled through the enable input 132. The capacitor 126 slowing discharges by current being draw from the charge on the capacitor 126 by the enabled module 102, thus the voltage on the capacitor 126 drops in proportion thereto. Once the voltage on the discharging capacitor 126 is less than or equal to the reference voltage 112, the output 110 will change logic levels. The digital integrated circuit device 100 may be placed in a "sleep mode" during this discharge process and then awakened by the logic level change at the output 110. A discharge resistor 124 may be added across the capacitor 126 to ensure a more accurate and controlled discharge rate. Enable inputs 128 and 130 may be coupled together as one input signal.

[0021] According to another exemplary embodiment of the invention, a basic timer may be implemented by coupling the capacitor 126 to connection 120, and disabling the internal current source 104 with a disable signal to the enable input 128. Connection 120 may be defined as a digital output through transistors 116 and 118, and the capacitor 126 is charged to substantially rail voltage 130, *e.g.*,  $V_{DD}$ . Once the capacitor 126 is substantially charged to the rail voltage 130, the transistors 116 and 118 are turned off (tri-stated or decoupled from the connection 120 and the internal current source 104 is enabled through the enable input 128. The capacitor 126 slowing discharges through the internal current source 104 and the voltage on the capacitor 126 drops in proportion thereto. Once the voltage on the discharging capacitor 126 is less than or equal to the reference voltage 112, the output 110 will change logic levels. The digital integrated circuit device 100 may be placed in a "sleep mode" during this discharge process and then awakened by the logic level change at the output 110. Use of the internal

current source 104 instead of the resistor 124 may result in a less accurately timed period due to process and temperature variations that may affect the internal current source 104 more than the external resistor 124. Enable inputs 128 and 130 may be coupled together as one input signal.

[0022] According to another exemplary embodiment of the invention, a programmable timer may be implemented by presetting the voltage on connection 120 to substantially the voltage rail 114, *e.g.*,  $V_{SS}$ , with the transistor 116. Since the capacitor 126 is coupled to connection 120, it will be set to substantially the voltage rail 114. Then transistor 118 is turned on to controllably charge the capacitor 126 for a predefined time. During this charging time, the module 102 and/or current source 104 may be disabled to reduce parasitic current draw. A charging time constant may be determined from the series RC time constant combination of resistor 122 and capacitor 126, and the discharge time from the parallel RC time constant combination of resistor 124 and capacitor 126. The value of voltage reference 112 also determines the programmable time constant(s). The charging and discharging time constants may be symmetrical or asymmetrical. Resistor 122 is optional and the invention operates satisfactorily without this resistor. The resistor 122 preferably may enhance functionality of the invention.

[0023] A calibration process of this programmable timer may be performed with the digital integrated circuit device 100 is in an active timing mode. Calibration may be determined from a main active clock source (not shown), *e.g.*, internal oscillator or external crystal oscillator. Generally, a constant supply voltage may be assumed, however, in battery applications, the charge and discharge periods may be periodically re-calibrated to ensure sleep timer accuracy.

[0024] According to another exemplary embodiment of the invention, a programmable low-voltage detection (PLVD) circuit may be implemented by charging capacitor 126 to the rail voltage 130, then activating the module 102. The capacitor 126 may discharge through the module 102, the activated current source 104, and/or the resistor 124. Discharge timing is such that if a low (battery) voltage is present, the voltage on the capacitor 126 will discharge below the reference voltage 112 within a certain time period and there will be a change in logic level at the output 110. This logic level change may be used to indicate a low battery voltage condition. It is also contemplated and within the scope of the invention that the capacitor 126 may be charged at certain time intervals short enough so as to maintain the voltage on the capacitor above the reference voltage 112.

[0025] According to still another embodiment of the invention, measurement of temperature may be determined from the way change in temperature affects the voltage reference and the internal current source. Temperature dependency of the voltage reference is substantially linear, and, if the temperature change is relatively small, the internal current source will also be substantially linear. Generally, values of the voltage reference and the internal current source may be measured at a known temperature. Then the deviation from that known temperature may be approximately determined from either of the following relationships:

$$\Delta T = (V_{IL} - V_{STANDARD})/(-1.25 \times 10^{-3}), \text{ or}$$

$$\Delta T = (I_{SINK} - I_{STANDARD})/(140 \times 10^{-12})$$

where  $\Delta T$  is the temperature deviation from a known temperature,  $V_{IL}$  the trip voltage, i.e., value of the voltage reference at the temperature deviation;  $V_{STANDARD}$  is the value of the voltage

reference at the know temperature,  $I_{\text{SINK}}$  is the value of the internal current source at the temperature deviation, and  $I_{\text{STANDARD}}$  is the value of the internal current source at the know temperature.  $I_{\text{SINK}}$  may be determined by how it affects the timing of a precision timer circuit, or determined from the voltage drop measured across a precision resistor in series with the internal current source (*i.e.*, use Ohms law to obtain the current value).

[0026] The invention, therefore, is well adapted to carry out the objects and attain the ends and advantages mentioned, as well as others inherent therein. While the invention has been depicted, described, and is defined by reference to exemplary embodiments of the invention, such a reference does not imply a limitation on the invention, and no such limitation is to be inferred. The invention is capable of considerable modification, alternation, and equivalents in form and function, as will occur to those ordinarily skilled in the pertinent arts and having the benefit of this disclosure. The depicted and described embodiments of the invention are exemplary only, and are not exhaustive of the scope of the invention. Consequently, the invention is intended to be limited only by the spirit and scope of the appended claims, giving full cognizance to equivalents in all respects.
